The effects of active labour market policies in Sweden: What is the evidence?

by

Lars Calmfors, Anders Forsslund, and Maria Hemström

2002-12-06

Summary

The Swedish experiences of the 1990s provide a unique example of how large-scale active labour market programmes (ALMPs) have been used as a means to fight high unemployment. This paper surveys the empirical studies of the effects of ALMPs on (un)employment in Sweden. The main conclusions are: (i) there is hardly any evidence for a positive effect on matching efficiency; (ii) there are some indications of positive effects on labour force participation; (iii) subsidised employment seems to cause displacement of regular employment, whereas this appears not to be the case for labour market training; (iv) it is unclear whether or not ALMPs raise aggregate wage pressure in the economy; (v) in the 1990s, training programmes seem not to have enhanced the employment probabilities of participants, whereas some forms of subsidised employment seem to have had such effects; and (vi) youth programmes seem to have caused substantial displacement effects at the same time as the gains for participants appear uncertain.

On the whole, ALMPs have probably reduced open unemployment, but also reduced regular employment. The overall policy conclusion is that ALMPs of the scale used in Sweden in the 1990s are not an efficient means of employment policy. To be effective, ALMPs should be used on a smaller scale. There should be a greater emphasis on holding down long-term unemployment in general and a smaller emphasis on youth programmes. ALMPs should not be used as a means to renew unemployment benefit eligibility.

* Lars Calmfors is professor of international economics at the Institute for International Economic Studies, Stockholm University. Anders Forsslund is a senior research fellow and deputy director of IFAU (the Swedish Office of Labour Market Policy Evaluation). Maria Hemström is a senior research fellow at IFAU. The authors are grateful for comments on previous versions from Jonas Agell, Susanne Ackum Agell, Jim Albrecht, Dan Andersson, Per-Anders Edin, Bertil Holmlund, Per Johansson, Katarina Richardson, Karl-Martin Sjöstrand, Alfons Weichenrieder, and Johnny Zetterberg.
During the last decade there has been an increasing international interest in active labour market policies, i.e. measures to raise employment that are directly targeted at the unemployed. According to conventional definitions, these policies comprise: (i) job broking activities with the aim of improving the matching between vacancies and unemployed; (ii) labour market training; and (iii) subsidised employment (job creation). Recommendations to expand the use of these policies have become standard from international bodies, such as the OECD and the EU Commission (e.g. OECD, 1994; European Commission, 2000). In the EU, the European Council agreed in 1997 on an employment strategy that includes active labour market policy as a key ingredient,¹ and many member states have followed these recommendations.²

The recent interest in active labour market policies motivates a thorough evaluation of how successful the active labour market programmes (henceforth denoted ALMPs) in various countries have been. Sweden is then a case of particular interest, as this is the country where the focus on active labour market policy has been the greatest. Partly this reflects an old tradition; partly it was the response to a sudden and steep increase in unemployment in the early 1990s. At their peak in 1994, ALMPs in Sweden encompassed more than 5 per cent of the labour force and expenditures accounted for more than 3 per cent of GDP.

The Swedish case is interesting from the point of view of evaluation because a large number of studies of the effects of ALMPs have been made. Recent studies have been able to draw on an internationally unique data material: the National Labour Market Board (Ams) provides a longitudinal data set with the event history of all unemployed individuals registered at the public employment offices since 1991. This makes it possible to trace the effects of participation in ALMPs for a very large number of persons over long periods. The Swedish experiences are of great interest also because they illustrate clearly the interdependence between "passive" unemployment support and "active" measures, which has been the subject of much recent policy discussion (see e.g. European Commission, 2000).

² This is evident from the national action plans on employment. The plans for 2001 are available at http://europa.eu.int/comm/employment_social/news/2001/may/naps2001_en.html.
This paper surveys the evidence on the employment effects of Swedish active labour market policy. The focus is on how ALMPs affect regular employment, i.e. employment excluding participation in programmes. The motivation for this focus is that employment generation is widely considered to be the primary aim of active labour market policy, even though there are also other goals, such as social-policy aims of mitigating the consequences of open unemployment and contributing to a more even income distribution, as well as additional macroeconomic aims of, for example, raising productivity growth. The results from studies of Sweden will be compared with the evidence from macroeconomic studies based on cross-country or panel data for the OECD countries. Such a comparison is highly relevant, because the latter studies, originating with Layard et al. (1991), have usually been interpreted to give strong empirical support for the effectiveness of active labour market policy as a means of raising employment.

The paper is structured as follows. Section 1 gives a background picture of how ALMPs have been used in Sweden. Section 2 identifies a number of theoretical mechanisms. Section 3 surveys Swedish microeconometric studies of the effects on the individuals participating in ALMPs, and Section 4 surveys Swedish macroeconomic studies of the general-equilibrium effects. Section 5 reviews the studies based on cross-country or panel data for OECD countries. Section 6 sums up the results and draws policy conclusions.

1 Active labour market policy in Sweden

There is a long tradition of active labour market policy in Sweden. In the beginning of the 20th century, municipal employment offices were built up (Thoursie, 1990). In the depressions of the inter-war years, the government organised relief works and special youth jobs. In 1948, the foundations of modern labour market policy were laid when the National Labour Market Board was instituted.

1.1 The thinking behind labour market policy

The thinking around Swedish labour market policy was, at least before the 1990s, guided mainly by the principles laid out by two trade union economists,
Gösta Rehn and Rudolf Meidner, in the late 1940s and early 1950s. They saw active labour market policy as a necessary ingredient in a policy mix designed to combine low inflation, full employment and wage compression. They worried that an anti-inflationary demand-management policy would cause unemployment in low-productivity sectors. To avoid that, they recommended labour market re-training and other mobility-enhancing measures, so that workers threatened by unemployment in low-productivity sectors could be transferred to high-productivity sectors, relieving labour shortages there.

The original focus in post-war Swedish labour market policy was thus on increasing labour mobility. However, over time in the 1960-1990 period the emphasis gradually shifted in the direction of counteracting all types of unemployment. In the late 1960s and early 1970s, the objective of eliminating remaining “islands of unemployment” through selective job creation programmes became more important (Meidner, 1969). Gradually, it also became a more important aim to hold down unemployment in general in recessions. This development seems to be explained by generally rising ambitions in employment policy (Lindbeck, 1975; Calmfors and Forslund, 1990).

The motive of holding down open unemployment in general came to dominate completely in the 1990s. In the early 1990s, Sweden entered its deepest recession in the post-war period with regular employment falling by 13 per cent between 1990 and 1994. In this situation, placement in ALMPs became the main short-run policy instrument to counteract the rise in open unemployment. Policy was also to a large extent guided by the social-policy objectives of providing income support for the unemployed: formally, unemployment compensation could not be had for more than 14 months for the majority of the work force, but eligibility could be renewed through participation in ALMPs. There is ample evidence that programme placements were systematically used to this end (e.g. Carling et al., 1996; Sianesi, 2001).

An important side objective of Swedish active labour market policy has always been to mitigate the moral hazard problems of a generous unemployment insurance: by making payment of unemployment compensation conditional on accepting regular job offers or placement offers in ALMPs from the public.

employment offices, active labour market policy has been used as a work test for the recipients of unemployment compensation.

1.2 The various programmes
Originally, labour market training mainly consisted of vocational training programmes, but over time schemes containing more general education have become more important. In recent years, also education in Swedish for immigrants has formed part of labour market training. Computer activity centres, which were introduced in 1995, represent another innovation; in addition an IT program (Swit) was launched by the government in 1998 in cooperation with the Confederation of Swedish Industries. The duration of training programmes has usually been six months. Participants have received training grants equivalent to unemployment compensation. From the second half of the 1980s, it became possible for unemployed individuals to requalify for unemployment compensation through participation in training programmes. In 2000, this possibility was abolished for all labour market programmes.

There have been many types of subsidised employment schemes over the years. The classical measure has been relief works. They consisted of temporary jobs (around six months), which were usually arranged in the public sector, but to some extent also in the private sector, and where employers obtained a subsidy for employing individuals selected by the public employment offices. The participants were paid wages according to collective agreements. Relief works were used up to 1998, when they were abolished.

In the 1990s, relief works were largely replaced by so-called work experience schemes. These consisted of activities that "would otherwise not have occurred" and were often arranged by various non-profit organisations. The aim was to organise activities that would not crowd out regular employment. Participants in work experience schemes received unemployment compensation. Recruitment subsidies and (more recently) employment subsidies are programmes that are more similar to regular employment. Both programmes have entailed wage subsidies to employers for hiring unemployed (mainly long-term unemployed). Participants have been paid regular wages according to collective agreements.
Another type of subsidised employment is self-employment grants. These grants, which consist of unemployment benefits for up to six months, are given to unemployed persons to start their own businesses after scrutiny by the employment offices. These have also arranged entrepreneurial training for the participants.

Other programmes can be characterised as work practice programmes. In our survey of empirical results, we include these in job creation activities, but work practice programmes are supposed to have also a training content. Various types of youth schemes belong to this category. The first youth programme was youth teams introduced in 1984. They were followed by “schooling-in slots”. During 1992 youth practice was introduced. This programme rapidly reached large volumes. The programme was targeted at youth below the age of twenty-five. As was the case for work experience schemes, there were clear instructions to avoid displacement effects.

Other examples of work practice programmes were practice for immigrants and practice for academic graduates, which were similar in spirit to youth practice, but with different target groups. Yet another work practice programme was work placement schemes, which replaced practice for immigrants, practice for academic graduates and youth practice in 1995.

Resource jobs were introduced in 1997 and entailed subsidies to employers for temporarily (six months with an option to prolong it by three months) hiring unemployed persons. The participants were mainly supposed to work, but were in addition supposed to take part in training and to actively search for jobs. The wage rate was capped at what roughly corresponds to 90 percent of the participant’s previous income.

Trainee replacement schemes involved subsidies during at most six months to employers, who paid for training for an employee and hired a replacement (who received a wage according to collective agreements). Hence, trainee replacement schemes can be classified as both training and job creation.

The only programme that has been used over the entire period under study is labour market training. All other programmes have either been instituted during the period and/or ended during it. Relief works were abandoned in 1998, recruitment subsidies were used between 1981 and 1997, work experience schemes were used between 1993 and 1998, work placement schemes

Finally, a reform took place in 2000, when an activity guarantee was introduced. This programme is targeted at persons who are or are at risk of becoming long-term unemployed (or, more precisely, long-term registered at the public employment service). Within the programme the participants are given some full-time activity, e.g. job search, until they find a job or enrol in regular education. This reform was made in connection with the abolishment of the earlier possibility to renew benefit eligibility by participating in ALMPs.

1.3 The empirical picture

Figures 1-3 illustrate how the programme volumes have developed over time.

Figure 1: Open unemployment and programme participation (shares of labour force), 1970–2001

Figure 1 shows open unemployment and total participation in ALMPs. The picture is one of a slow trend-wise growth in the size of ALMPs in the 1970s and 1980s, but there is also a cyclical pattern. The large expansion in the 1990s in connection with the steep rise in unemployment also stands out. Towards the
end of the 1990s, when unemployment came down, the programme volumes were reduced again.

Figure 2 depicts total unemployment (the sum of open unemployment and participation in ALMPs) and the accommodation ratio (the ratio between programme participation and total unemployment). In the 1970s and 1980s, the accommodation ratio was of the order of magnitude of 0.4–0.5, but it fell in the 1990s. Although programmes expanded strongly then, they did not increase proportionally to the rise in unemployment. In 2000, the accommodation ratio was around 0.2.

Figure 2: The accommodation ratio (right-hand scale) and total unemployment, 1970–2001

Notes: Total unemployment is defined as the sum of open unemployment and total participation in ALMPs. The accommodation ratio is defined as the ratio of programme participation to total unemployment.

Sources: Participation in ALMPs: The National Labour Market Board; Unemployment and the labour force: Statistics Sweden.

Figure 3 shows the development of various programme types. In the 1970s and 1980s, training encompassed more persons than subsidised employment. The only exception was the recession in the first half of the 1980s. The steep increase in unemployment in 1991-92 was first met by a large expansion of training programmes, but later there were large increases in schemes of subsidised employment and practice. Recently, training programmes have again become relatively more important.
1.4 Swedish ALMPs in an international perspective

Table 1 provides an international perspective. In both the 1986–90 and 1991–95 periods, Sweden spent more on active labour market policy than any other country. The difference is especially marked in the 1991–95 period, when expenditures in Sweden amounted to 1.79 percent of GDP, one percentage point higher than the EU average. Expenditures in Sweden were reduced in 1996–2000 when unemployment fell, but still amounted to as much as 1.30 percent of GDP, which was well above the EU and OECD averages. In this period, Ireland, however, spent slightly more on active labour market policy.

The table also shows that Sweden had the largest share of active expenditures in 1986–90, when it was 59 percent, more than double the EU and OECD averages. The share subsequently fell, but remained substantially above the EU and OECD averages.

What finally stands out is the larger emphasis in Sweden than in most other countries on labour market training. 42 percent of the expenditures on ALMPs in Sweden have been on training, compared to EU and OECD averages of 27 and 28 percent, respectively. Only a few countries (New Zealand, Canada, Denmark, and the Netherlands) have spent larger fractions of active expenditures on training than Sweden.

2 A theoretical framework

ALMPs can have a number of effects on employment. Some of the effects are intended, whereas others are unintended. To sort them out, we use a modified version of the Layard et al. (1991) theoretical framework for analysing equilibrium real wages and unemployment, as set out by Calmfors (1994).

In Figure 4 we distinguish between three curves. A downward-sloping employment schedule shows how regular labour demand (labour demand excluding participation in ALMPs) depends negatively on the real wage. An upward-sloping wage-setting schedule shows how wage pressure depends positively on regular employment. (The underlying assumption is that higher regular employment is associated with a higher probability of finding a job if an employee is separated from his present job. This gives employees a better outside option when bargaining with the present employer, which makes it possible to obtain a higher wage.) The intersection of the two curves gives the equilibrium levels of real wages and regular employment. In addition, a vertical line shows the labour force. By deducting participation in ALMPs from the labour force, and comparing the outcome with regular employment, one obtains open unemployment.

Figure 4: Wage setting and employment

The analytical framework in Figure 4 can be motivated in several ways. The simplest possibility is to view the employment schedule as an ordinary
stock demand for labour, following from the usual marginal productivity condition. The wage-setting schedule may be viewed as the (steady-state) outcome of either collective wage bargaining or unilateral employer decisions on wages in an efficiency-wage framework. However, for some applications it is more worthwhile to see the employment schedule as a (steady-state) reduced form derived from a framework where vacancies and unemployed need to be matched along the lines of Pissarides (1990) and Mortensen and Pissarides (1994). In this case, it is convenient to regard wage setting as the outcome of agreements between employers and individual employees.

With the help of the above framework, we shall analyse various effects of ALMPs. Following Calmfors (1994), we distinguish between: (i) effects on the matching process; (ii) effects on the competition for jobs; (iii) productivity effects; (iv) effects on the allocation of labour between sectors; (v) direct crowding-out effects on regular labour demand; and (vi) accommodation effects on wage setting.

### 2.1 Effects on the matching process

The aim of the job-broking and counselling activities for the unemployed by the public employment offices is to make the matching process more efficient, i.e. to increase the number of successful matches at given numbers of vacancies and job seekers. This is often regarded as the primary function of active labour market policy.

A more efficient matching process shifts the employment schedule in Figure 4 to the right, which tends to raise both employment and the real wage. The explanation is that an increase in matching efficiency increases the probability of filling a posted vacancy at any point of time. Hence, the expected return to posting vacancies increases, and therefore more vacancies are posted. This results in higher employment.

An increase in matching efficiency also shifts the wage-setting schedule to the right, which works in the direction of reducing the real wage and increasing employment. The reason is that the higher is matching efficiency, the better is the firm’s bargaining position vis-à-vis the employee, because a vacancy can then be more quickly filled if the employee quits because of disagreement over

---

4 The exposition builds on Pissarides (1990), Mortensen and Pissarides (1994), and Romer (1996), Ch. 10. See also Holmlund and Lindén (1993) and Fredriksson (1997) for direct applications to ALMPs.
the wage. Hence, a higher matching efficiency means that the firm is able to negotiate a lower real wage at each level of employment.\footnote{One might think that an increase in matching efficiency should also have an effect working in the opposite direction because it will enable a quitter to find a new job more quickly. This is not, however, the case if employment is held constant. The probability for a job seeker to find a new job equals the aggregate number of matches divided by the aggregate number of job seekers in the economy. In a steady state with given employment (and a given number of job seekers), the number of matches is also given, if we assume – as is conventionally done – that the number of separations from jobs equals a fixed quit rate times employment. It follows that at a given aggregate employment level, the probability for a job seeker to find a job is independent of matching efficiency.}

As a higher matching efficiency will shift both the employment and wage-setting schedules to the right, this effect must increase employment, whereas the effect on the real wage is ambiguous.

One should indeed expect active labour market policy in the form of job broking and counselling activities as well as completed labour market training to increase matching efficiency. This is the desired \textit{treatment effect}. But there may also be a \textit{locking-in effect} of training or job creation programmes working in the opposite direction if the participants do not exit from the programmes before they are completed. This effect tends instead to shift the employment and wage-setting schedules to the left. The consequence is then a tendency to lower regular employment (whereas the impact on the real wage is still unclear). Whether or not the treatment effect dominates the locking-in effect is an empirical issue.

\subsection{2.2 Effects on the competition for jobs}

Quite apart from their effect on matching efficiency, ALMPs may affect the degree of competition for the available jobs by making participants more competitive. This may result from several mechanisms (Layard et al., 1991; Nickell and Layard, 1999). Participation in an ALMP may help to maintain the motivation to seek actively for work, i.e. counteract the discouraged-worker effect of unemployment. The competition for jobs is also stimulated if ALMPs help to preserve or increase the skills of the unemployed. And employers may in general perceive participants in ALMPs as more attractive than the openly unemployed.

As a result, ALMPs may have a positive effect on labour force participation. In \textit{Figure 4}, the labour supply schedule, showing the size of the work force, is then shifted to the right. The wage-setting schedule is also shifted to
the right. The reason is that there are more workers competing for the same number of jobs: a given level of regular employment is thus associated with a lower job-finding probability, which worsens the outside option of employees in wage bargaining.

So, ALMPs may exert a positive employment effect by increasing the competition for the available jobs. But just as with matching efficiency, this requires that the earlier discussed treatment effects are stronger than the locking-in effects.

### 2.3 Effects on the productivity of job seekers

Another desired effect of ALMPs is to increase the productivity of job seekers (Calmfors, 1994). This is the aim of labour market training as well as of various work experience programmes, but such an effect may also arise because of on-the-job training in a pure job creation scheme.

An increase in the productivity of job seekers shifts the segment of the marginal product curve that applies to job seekers (non-employed workers), i.e. the segment to the right of the intersection with the wage-setting schedule, in Figure 4 upwards. Everything else equal, this results in an increase in regular employment. But an increase in the productivity of job seekers may also cause their reservation wages to increase. If this occurs, the wage-setting schedule is also shifted upwards in this segment, which tends to offset the positive effect on regular employment. If the wage-setting schedule is shifted upwards by as much as the employment schedule, the net effect on regular employment is zero. Whether or not such effects are important is an empirical issue.

### 2.4 Effects on the allocation of the work force

A fourth intended effect of ALMPs can be to change the allocation of the work force between different sectors. According to the Rehn-Meidner model (see Section 1.1), the original goal of active labour market policy in Sweden was to transfer labour from stagnating low-productivity sectors with high unemployment to expanding high-productivity sectors with low unemployment through training programmes and other mobility-enhancing measures. Such policies will reduce wage pressures substantially in low-unemployment sectors, whereas wage pressures will increase only a little in high-unemployment sectors if the sector-specific wage-setting schedules are convex (Calmfors, 1995;
Fukushima, 1998). The result will be a rightward shift of the aggregate wage-setting schedule.

2.5 Direct crowding-out (displacement) effects
An unintended side effect of ALMPs is that they may crowd out regular labour demand (see e.g. Dahlberg and Forslund, 1999). This is likely to apply mainly to schemes of subsidised employment. Such crowding-out (displacement) effects presuppose that the unemployed who are hired are substitutes – and not complements – to other employees in production, so that the hiring of unemployed workers lowers the marginal product of regular employees.

In terms of Figure 4, direct crowding-out means that the employment schedule (the regular labour demand schedule) is shifted to the left. This tends to reduce both the real wage and regular employment.

The direct crowding-out effects need to be seen in association with the competition effects in Section 2.2. Even if there is complete crowding-out, there may be a positive employment effect to the extent that employment of long-term unemployed (outsiders) crowds out employment of insiders, so that the latter group meets more competition. The crowding-out effects may thus be necessary to reach the desired competition effects.

2.6 Accommodation effects on wage setting
Participation in ALMPs may also give rise to unintended side effects on wage setting because the welfare of the unemployed is affected. There are several possible effects:

- Participation in ALMPs may imply higher incomes for job seekers than would otherwise be the case, if compensation there is higher than the unemployment benefit (Calmfors and Nymoen, 1990; Calmfors and Forslund, 1991).
- Participants in ALMPs may experience a higher degree of psychological well-being than the openly unemployed, because programme participation is considered more meaningful (Korpi, 1997).
- If programme participation is expected to improve future labour market prospects, it will increase the expected future welfare of participants (Calmfors and Lang, 1995).
If programme participation means that the participants renew their eligibility for unemployment compensation (the earlier Swedish system) or is used as a supplement to extend the period of income support beyond the maximum unemployment benefit period, this will also raise the future expected incomes of the unemployed.

All the above effects reduce the welfare difference between having and not having a job. Hence, they increase wage pressure. In terms of Figure 4, the wage-setting schedule is shifted upwards. This means higher real wages and lower regular employment. This can be seen as an accommodation effect, which leads to indirect crowding-out of regular jobs.

However, there may also be a "control effect” working in the opposite direction (Jackman, 1994). Participation in ALMPs and active job search on part of the unemployed are requirements to receive unemployment compensation. So for some unemployed individuals, programme participation means a welfare loss because they can no longer allocate their time freely. Judging from the reactions of some of the unemployed, the so-called activity guarantee in Sweden, which was initiated in 2000, may to some degree work in this way (see Section 1.2). To the extent that this is the case, the above effects are reversed, and the wage-setting schedule tends to be shifted downwards.

2.7 The effects of ALMPs
Our analysis is summarised in Table 2, which shows the expected direction of the various effects. We have put question marks where the expected effects may theoretically be counteracted by other effects. This applies to matching efficiency and the competition for jobs, where treatment and locking-in effects work in opposite directions. It applies also to the accommodation effects on wage setting, where the wage-rising effects may be counteracted by control effects. We have indicated with parentheses that the positive productivity effects may be offset by increased reservation wages.

The net employment effect of ALMPs is obviously an empirical issue. The rest of the paper is devoted to a survey of the empirical research on the employment effects of ALMPs in Sweden. These studies are in principle of two types: microeconomic and macroeconomic. The microeconomic studies evaluate the effects of participation in ALMPs for the participating individuals, whereas the macroeconomic ones examine the aggregate general-equilibrium effects.

The microeconomic studies can benefit from data sets with a large number of observations. By examining whether participation in ALMPs implies larger employment chances as compared to non-participation, these studies can give indications of the effects on matching efficiency, the competition for jobs, the productivity of the participants and the re-allocation of labour. Knowledge on these effects can also be obtained by examining how programme participation affects the mobility of job seekers, their search behaviour and the attitudes of employers.

The microeconomic studies of the effects on individuals do not by definition capture the effects of ALMPs on non-participants. These general equilibrium effects can only by examined in macroeconomic studies. This applies, for example, to the direct crowding-out effects and the accommodation effects on wage setting. Only the macroeconomic studies can give the full picture of the effects of ALMPs on employment and wages. But a problem with these studies is that the number of observations is often small.

The two types of studies complement each other. The two subsequent sections summarise the studies of these types that have been made in Sweden.

### 3 Microeconomic studies

This section surveys the evidence from microconometric studies of the effects of ALMPs on the participants. We focus on the effects on regular employment,
but look also at the effects on income (since income depends positively on employment).

The issue is how the labour market outcome of participants compares to the outcome that would have prevailed had they not participated in an ALMP. The crucial element in such an evaluation is to find a comparison group whose outcome equals the counterfactual needed to establish the treatment effects. Evaluations are plagued by potential problems of sample selection bias. There is a large literature on this evaluation problem, which was initiated by Heckman (1979) (see e.g. Heckman et al., 1999). However, the set-up of the Swedish labour market policy differs from the one usually considered in the evaluation literature. As discussed in Section 1.2, there is a wide array of continuously ongoing programmes for the unemployed. All unemployed may, theoretically, participate and most long-term unemployed do so repeatedly during their unemployment spell(s). Therefore, it is difficult to find a proper comparison group who neither has participated nor will participate in the future in an ALMP. The choice for an unemployed is to participate in a programme now or later, rather than now or never (see Carling and Larsson, 2000a; and Sianesi, 2001a, for a further discussion). As a consequence, the mere existence of programmes may influence the behaviour of non-participants also.

Also, the fact that most long-term unemployed will ultimately participate in (several) ALMPs makes it difficult to evaluate the long-term effects. First, it is difficult to relate estimated effects to specific ALMPs. Second, the number of openly unemployed who have never participated, and can therefore be used as a comparison group, will be very small. This problem is genuine if treatment effects are not immediate and rapidly transient (Carling and Larsson, 2000b). Third, as every long-term unemployed is likely sooner or later to participate in an ALMP, the problem of sample selection bias is exacerbated: job seekers with large difficulties of finding a job tend to be over-represented among ALMP participants (Sianesi, 2001b).

The evaluation literature on Swedish ALMPs since the mid-1980s must therefore be interpreted with caution. It is possible that these evaluations analyse the effect of participating at a specific point in time rather than later or in a certain programme rather than in another instead of the effect of participation compared to non-participation as such.
The early Swedish evaluation literature proceeds from small and “special” data sets based on survey data and/or information from personal files kept at the employment offices. The research of the 1990s leans heavily on the event data base Händel (which comprises information on all registered job-seekers since 1991) and sometimes combines this with register or survey data on employment and income. Statistics on search behaviour and employer attitudes are based on survey data.

This part is organised as follows. Section 3.1 looks at treatment effects of labour market training (LMT), whereas Section 3.2 focuses on the effects of subsidised employment. Section 3.3 summarises the evidence on the effects of ALMPs on the search behaviour of participants, and Section 3.4 reviews the studies of effects on employer attitudes.

### 3.1 Labour market training

The research on the effects of labour market training is summarised in Table 3.

Harkman, Johansson & Okeke (1999) LMT & computer activity centres, 1996 Register and survey data on 3000 20–54 years old participants. Random selection and representative sample Regular employment 1 year after programme Positive effect of LMT only if potential selection is not considered; no significant effect of computer activity centres

Larsson (2000) LMT, 1992–93 Register data on 600 20–24 years old participants. Non-participating comparison group through propensity score matching (i) Yearly income; and probability to (ii) obtain a job; or (iii) proceed to regular education 1–2 years after programme Significant, negative effects

Johansson & Martinsson (2000) Swit, 1999 Register and survey data on 4000 Swit participants. Comparison group = 7000 participants in similar traditional IT training Regular employment 6 months after programme Significant, positive effect

Okeke (2001) LMT, 1998–99 Register and survey data on a stratified subsample of participants. Non-participating comparison group through propensity score matching Regular employment 6 months after programme Significant, large positive effect

Richardson & van den Berg (2001) LMT, 1993–2000 Register data on a 1% random subsample of all who became openly unemployed 930101–000622 (5000 individuals of whom 665 participated in LMT). Bivariate duration model with individual heterogeneity Unemployment duration Significant, negative effect that vanished within two months after the training ended if unemployment duration is measured from the end of LMT; insignificant effect if unemployment duration is measured from the start of
Although results vary a lot between studies, some conclusions can be drawn. The estimated effects of labour market training differ between the 1980s and 1990s. Evaluations of training acquired during the first half of the 1980s suggest positive effects on participants’ employment and/or income. Evaluations of training that took place in the 1990s usually find instead insignificant or significantly negative effects.

Both Edin and Holmlund (1991) and Korpi (1994) estimated, using the same sample, the effects of labour market training for young people in the early 1980s. Edin and Holmlund found that training increased the re-employment probability in subsequent unemployment spells. Korpi found that training increased the duration of subsequent employment.

Axelsson and Löfgren (1992) analysed the impact of labour market training in 1981 on the (growth and level of) incomes obtained one–two years later. Fixed-effect estimates, using the entire sample, indicated that the yearly incomes of participants increased by as much as 21 percent the first and 30 percent the second year following training. The authors also found that returns were higher the longer the training. But the estimated effects decreased considerably – but were still sizeable – as the sample and/or methods were changed. The results further indicated that participants were, on average, more ambitious and motivated than non-participants. As the selection thus established was considered, estimates became unstable, divergent and sometimes implausible.

Regnér (1997) also analysed the effect on yearly incomes. Irrespective of the method used, the effects were negative after one and insignificant after three years. However, specification tests yielded varying results, and models...
that were just about accepted by one test were rejected by another. But the qualitative conclusions remained basically the same.

Three different evaluations of labour market training in the 1990s have been published by the National Labour Market Board. Harkman et al. (1996) estimated the effect of training in 1993 on the probability of having a regular job later on. The results differ depending on the method used. According to one method, training had no effect after six months, but a significant and positive effect after three years. However, as selection problems were considered, the authors found no significant effect on the probability of having a job at either point in time.

Harkman (1997) analysed the effect of training undertaken in 1994 on the probability of having a job two and a half years later. Although selection problems were not considered, no effects of training in general were found. The analysis also compared the effects of short and long spells of training (with the limit set at 100 days). The short spells of training had a significant, negative impact on the employment probability, while long spells had a positive but insignificant effect. The difference in effect between short and long spells was, however, statistically significant, and amounted to 4 percent.

Harkman et al. (1999), finally, analysed the effect of training in 1996 on the employment probability one year later. Besides “traditional” labour market training, this evaluation looked also at the effect of training in computer activity centres. The results are hard to interpret, as participants (on average) have different prior unemployment and programme participation experiences than non-participants. The analysis of the effect of a single programme is further complicated by the fact that participants as a rule have participated in several programmes earlier. One way to handle this problem is to consider only persons without earlier programme participation. Such estimates indicate that computer activity centres had no significant effect, while participation in traditional training had a positive effect on the employment probability one year after programme completion. But these results must be interpreted cautiously because the effect is measured from the time of programme completion. This implies that the estimated effect will be positively biased.6

---

Larsson (2001) discusses the problems arising when effects are computed from the time of programme completion rather than from the programme start. The control group in the former case can be
Larsson (2000) estimated the effect of labour market training of young people in 1992–93. Her results convey a very discouraging picture. The effects on both future income and employment were significantly negative. In addition, the transition probability to regular education was lower among participants in training than among non-participants.

Johansson and Martinsson (2001) studied a programme called Swit, which was a joint project between the Swedish government and the Federation of Swedish Industries. It was initiated as an experiment during a two-year period (1997–99) with the aim of providing the Swedish industry with IT-skilled personnel. The set-up was non-traditional and combined traditional education and practice at host companies. The employment effects were compared with the effects of more conventional IT training run by the National Labour Market Board. The results indicated that Swit participants had a 20 percent higher probability to find a regular job than did participants in conventional IT training.

Okeke (2001) studied the effect of participation in training in 1998–99. According to the study the effects on participants’ employment were large, positive, and significant. But once again the results are hard to interpret, as it is not clear from the presentation how the control group has been selected, but the procedure used might imply a positive bias.

Richardson and van den Berg (2001) analysed the effect of training undertaken in 1993–2000. They found a significant negative effect on the duration of unemployment when the duration was measured from the end of the programme. When duration instead was measured from the start of the programme, the effect was insignificant. This suggests that a negative locking-in effect of labour market training more or less offsets a positive treatment effect once the programme had been completed.

chosen in two ways: Programme participants can be compared to either (i) non-participants who became unemployed at the same time as the participants and were unemployed both at the programme start and completion; or (ii) non-participants who at the time of programme completion had been unemployed for as long as the participants at the time of the programme start. Both procedures are likely to give a positive bias in the estimation of the treatment effect. In the first case, non-participants with a small job-finding probability tend to be over-represented in the sample (because they did not find a job during the programme period). In the second case, the participants have a longer time to search for jobs, because they can search also while participating in the programme.

7 However, the analysis in Fredriksson and Johansson (2002) shows that the procedures used in this study results in a negative bias in the estimated programme effects because the control group is selected in such a way that all spells end in employment.

8 See the discussion in footnote 6, which is applicable also to Okeke’s study.
Sianesi (2001b) estimated the effect of participating in training in the 1994–99 period. The comparison made in the study is between “participation now” and “waiting in open unemployment”. She found that the effect on the participants’ employment rate was significantly negative until 30 months after the end of the programme; later the effect was insignificant. Also, the probability of collecting unemployment benefits in the future was significantly higher for participants than for non-participants.

Another observation refers to the differences between short-run and effects of labour market training. The short-run effects are often insignificant or even negative. However, with a time horizon of a few years the estimated effects are more positive (1980s) or are, at least, no longer negative (1990s). A conceivable explanation is that training increases the reservation wages of participants (see Section 2.3). However, Richardson and van den Berg (2001) found a different pattern. According to their study, the treatment effect of training vanishes after two months. The authors suggest that the short-run treatment effect could be due mainly to extra placement efforts on the part of employment officers.

There is some evidence to suggest that income and employment effects increase with the length of training. But here the amount of research is very small.

3.2 Subsidised employment

There are a number of studies on the effect of subsidised employment, of which a few look also at the effect of labour market training. However, given the amount of different job creation programmes, less is known about the specific effect of single programmes than about labour market training. The studies of subsidised employment programmes are surveyed in Table 4.

</table>

Some of the studies in Table 4 have tried to evaluate the effects on subsequent employment of participation in various job creation programmes as compared to open unemployment, whereas other studies have tried only to compare various programmes with each other (but not with open unemployment) or to study the effect of participating in a programme at a given point of time rather than later. The latter studies avoid the problem that most long-term unemployed will sooner or later end up in a programme, which makes it hard to find a comparison group of non-participants (see the discussion in the introduction to Section 3).

Sehlstedt and Schröder (1989) found that recruitment subsidies improved the labour market situation of young people, provided that programme partici-
pation constituted a part of a larger “plan” designed to improve their labour market prospects. But the effect of relief work was not significant.

Edin and Holmlund (1991) analysed, in addition to labour market training (see Section 4.1), the employment effects of relief work, using a sample of young people and displaced workers. One result was that relief work participants found regular employment at a slower pace than non-participants. But re-employment probabilities in subsequent unemployment spells were significantly higher for former relief-work participants than for non-participants. When Korpi (1994) used the same sample of youth to analyse the effects of relief work on the duration of employment, he found a significant positive effect.

Axelsson et al. (1996) analysed the relative efficiency of labour market training, work experience schemes, relief work and youth practice in terms of the employment probability within thirty days after the programme ended. There were no significant differences between labour market training, work experience schemes and relief work, while youth practice had a significantly larger impact on the short-run probability of leaving unemployment.

Harkman et al. (1999) analysed (in addition to labour market training and computer activity centres (see Section 4.1)) the effect of job creation schemes in 1996 on the probability of having a job one year later. Also here the results must be interpreted with caution because of the risk of biased estimates (see footnote 6). Another problem is that the number of first-time participants in other forms of subsidised employment than work experience schemes and work placement schemes was small. With these caveats, the results suggest that recruitment subsidies had the most favourable effects. Also work placement schemes and trainee replacement schemes seem to have had positive effects, while this was not the case for work experience schemes and relief work.

Three evaluations of self-employment grants were published in 1999–2001. Okeke (1999) analysed the enterprise survival rate, which we interpret as an indicator of the employment effect. She found no significant difference in the survival rate between enterprises started with and enterprises started without self-employment grants three years after the start-up. This can be interpreted as a positive result if one assumes that enterprises started by unemployed (as an alternative to unemployment) have worse prospects than enterprises started by
employees who choose voluntarily to leave their employment to exploit supposedly profitable opportunities. However, potential selection bias was not considered, and the estimates should therefore be interpreted with caution.

A more comprehensive analysis is presented in Carling and Gustafsson (1999). They found that the outflow to unemployment was half as large among those who had obtained self-employment grants as among those who had benefited from recruitment subsidies during 1995–97. This also supports the favourable impression of self-employment grants, as other evaluations (see the earlier discussion in this section) indicate that recruitment subsidies have had positive effects.

Okeke et al. (2001) compared the rate of survival (1998) for firms started with and without self-employment grants (1995). The difference in survival was insignificant, but a larger fraction of those who had received self-employment grants reported that they could make a living from the returns from their firms three years after the launching of the firm.

Larsson (2000) analysed the effect of youth practice, as well as of labour market training (see Section 3.1), in 1992–93. The results of youth practice were very similar to those of labour market training: incomes were 20–30 percent and employment probabilities 18–37 percent lower among former participants than among non-participants one–two years after the programme. 9 But, in contrast to labour market training, youth practice had no decreasing effect on the transition rates to regular education.

Carling and Richardson (2001) analysed the relative efficiency of eight different programmes in terms of employment probabilities. The results indicate that the programmes in which participants conduct regular work (recruitment subsidies, self-employment grants and trainee replacement schemes) or at least obtain practice at a regular workplace (work placement scheme) achieve the best results. Training (both ordinary labour market training and training at computer activity centres) and job creation programmes that do not constitute regular work (work experience schemes and relief work) perform less well in terms of subsequent regular employment. The same ranking holds for different

---

9 However, there is likely to be a negative bias in the estimated programme effects, as discussed in footnote 7.
sub-groups of unemployed and is not affected by the timing of programme entry. This suggests that the results are not due to selection bias.

Sianesi (2001b), finally, compared the effects of participation in six different programmes (including labour market training, see Section 3.1) in 1994–99. She found that it was (significantly) better to “wait in open unemployment” than to participate in “work practice” (work placement schemes and work experience schemes) or relief work in terms of subsequent probability of employment. Trainee replacement schemes and recruitment subsidies, however, were equally good and better, respectively, compared to waiting in open unemployment. A mirror image of this was that both work practice and relief work had a significant, positive effect on the probability to receive future unemployment compensation. This indicates that the possibility to renew unemployment benefit eligibility may have been an important reason for programme participation. Another aspect of this is that the most negative effects of programme participation arose for those who started a programme close to the time of benefit exhaustion (Sianesi, 2001a).

3.3 Search activity
The probability to obtain a job is influenced by the job applicants’ search activity. It is therefore of interest to study whether or not ALMPs influence search activity. This is the topic of a number of survey studies, which have examined the difference in search behaviour between programme participants and openly unemployed. The studies are summarised in Table 5.

</table>

Edin and Holmlund (1991) found that unemployed youths devoted fully seven hours a week to job search in the beginning of the 1980s. The corresponding figure for relief work participants was less than one hour. The same survey indicated that the number of search methods used by the unemployed (3.1 per week) was significantly higher than among relief workers (0.6 per week). The results in Sehlstedt and Schröder (1989) for youth search behaviour in the mid 1980s convey a similar picture.

Ackum Agell (1996) and Regnér & Wadensjö (1999) studied search behaviour among adults. Ackum Agell (1996) found that the unemployed are more active job seekers than programme participants. The fraction of active seekers is much (and significantly) higher among the unemployed (95 per cent) than among programme participants (57 per cent), and programme participants use fewer search methods. Among the unemployed, 30 per cent reported that they did not search at all during the survey week; the corresponding figure for programme participants was 68 per cent. Also this difference was statistically significant.

Regnér & Wadensjö (1999) found that the fraction actively searching jobs or being in contact with the public employment service was significantly higher among the openly unemployed (72 and 79 per cent, respectively) than among programme participants (53 and 63 per cent, respectively) during the four weeks preceding the interview. But the authors also found that persons who had participated in a programme during the preceding twelve months
searched significantly more than those who had not participated in any pro-
gramme during the same period. This suggests a negative locking-in effect on
search effort during programme participation, but a positive treatment effect
after completion of the programme.

Ackum Agell (1996) emphasised that participants have less time to search
for work than do non-participants. Also, it can be socially beneficial that par-
ticipants do not look for work if the programme forms part of a comprehensive
plan to improve their labour market prospects. But this conclusion no longer
holds if placement in ALMPs is used to renew eligibility for unemployment
insurance. Either way, the studies of search activity do suggest that ALMPs
cause temporary locking-in effects.

3.4 Employer attitudes

Employer attitudes towards different categories of job applicants is another
factor that influences the possibility of finding a job. Several survey studies
have examined the effect of ALMPs in this respect. The studies are summa-
rised in Table 6.

Agell & Lundborg (1995, 2002) have in two survey studies, undertaken in
1991 and 1998, asked personnel managers about their attitudes to unemployed
job seekers with and without prior participation in ALMPs. The fraction who
considered a long-term unemployed potentially less productive than a similar
job applicant without an unemployment history rose from 21 to 27 per cent
between 1991 and 1998. 18 per cent of the respondents in the 1991 survey also
considered applicants with prior participation in a labour market programme
potentially less productive than a similar applicant without unemployment ex-
periences. The questions in the 1998 survey were more specific about the ef-
facts of programme participation. Almost 15 per cent of the respondents con-
sidered a participant in labour market training potentially less productive than a
similar person without an unemployment history. The corresponding fraction
for participants in relief work and work experience schemes was 20 per cent.

---

11 This conclusion was based on estimates in which search behaviour was related to different individ-
ual characteristics. The outcome measure was a “search index” constructed from answers to questions
about search time and search methods. Information about programme participation at (i) the time of the
interview and (ii) the twelve months preceding the interview are two of the variables used to explain
individual search behaviour.
However, the differences between participants in various programmes and the openly unemployed were never significant.

In a survey reported by Klingvall (1998) only some 3 per cent of the responding employers stated that they would consider hiring an openly unemployed job applicant, while 30 (20) per cent stated that they would consider hiring a job seeker who had participated in labour market training (any other labour market programme). The differences were statistically significant.

Also the results in the survey reported by Behrenz (2001) suggests that employers consider open unemployment more negative than participation in labour market programmes: 4.2 per cent of the about 800 respondents said that they automatically discard applications from openly unemployed job seekers; the corresponding figures for participants in labour market training and participants in other programmes were 1.2 and 1.6 per cent, respectively. The differences between the figures for programme participants and openly unemployed were significant; the difference between training and other programmes was not.

Agell & Bennmarker (2002), finally, in survey questions answered by personnel managers at 885 workplaces found that participation in labour market training prolonged the time required for a stigma from unemployment to arise.

The survey studies of employer attitudes are the studies giving the most favourable results for the effects of ALMPs on individuals. Although questions and estimated effects differ, these studies suggest that employers judge former ALMP participants more favourably than unemployed who have not participated in programmes. This evidence also suggests that labour market training is preferred to the other programmes. It is notable that this favourable view of labour market training has no counterpart in the econometric results reported in Section 3.1. It is not clear exactly what this discrepancy reflects; possibly it can be explained by the fact that the survey studies of employer attitudes do not control for other factors or potential selection, which the econometric studies do.

4 Macroeconomic studies
This section surveys the macroeconomic studies of the total (general equilibrium) effects, of ALMPs in Sweden. Doing this we follow our earlier classification in Table 2.

There are some general methodological problems in the macroeconomic studies. It may be difficult to obtain precise estimates of effects because the number of observations that can be used in the econometric analyses is often small. Another problem is two-way causality. It is not only the case that ALMPs may affect (un)employment, but changes in the labour market situation may also trigger political decisions to adjust the volume of ALMPs. This may give rise to simultaneity bias and identification problems. We repeatedly return to how this issue has been handled in various studies below.

Section 4.1 reviews the macroeconomic evidence on the effects on the matching process. Section 4.2 discusses direct crowding-out (displacement)
effects and Section 4.3 the effects on labour force participation. Section 4.4 surveys the studies of aggregate wage-setting effects, which are the net of several of the effects discussed in Section 2. Section 4.5, finally, reviews reduced-form estimations of the total effects on (un)employment.

4.1 Beveridge curves, matching functions and migration relationships

A first type of macroeconomic studies directly shed light on the efficiency of the matching process. These are studies of Beveridge curves, matching functions and geographical mobility.

Somewhat surprisingly, only two studies of Sweden have looked at the effects of ALMPs on matching in a Beveridge curve context (Jackman et al., 1990; Calmfors, 1993). Neither of these studies show any effects of ALMPs on matching efficiency. But the main conclusion is that we largely lack knowledge of the Beveridge curve effects as none of the studies covers the 1990s.

There are two studies of matching functions, which relate the number of hirings to the numbers of vacancies and unemployed, on Swedish data. Edin and Holmlund (1991) found that programme participation contributes to matching, but that the effect is only half that of open unemployment. This suggests that locking-in effects dominate treatment effects of these programmes in the short run. Hallgren (1996) found that subsidised employment had a significant negative impact on matching, whereas the opposite was true for labour market training. But again the main conclusion is the lack of empirical knowledge.

Geographical mobility is one important dimension of the matching process. Hence, the effects of ALMPs on this variable may serve as a proxy for the effects on matching. Here, several studies have been made. They are summarised in Table 7.

| Table 7 The effects of ALMPs on geographical mobility |

12 The relevant relationship to look at is the one between vacancies and total unemployment (the sum of open unemployment and programme participation). Calmfors (1993) estimates how this relationship is affected by a change in the accommodation ratio (the ratio between programme participation and total unemployment). Jackman et al. (1990) study instead the relationship between vacancies and open unemployment, but their results are recalculated in Calmfors (1993).

13 The authors could not reject the hypothesis that relief work and labour market training have the same effect (and that this effect is half that of open unemployment). However, when the effects of training and relief work were estimated separately, it could not be rejected that training and unemployment have the same effect.
McCormick & Skedinger (1991) found that increased programme volumes at the regional level give rise to higher unemployment. The results may be interpreted in several ways, but the authors conclude that ALMPs have reduced geographical mobility.

Nilsson (1995), Westerlund (1997), and Heiborn (1998) all estimated models of migration between the Swedish counties. Nilsson found some evidence of locking-in effects: increased programme participation in a county led to a significant decrease in out-migration. Some of Westerlund’s estimates also pointed to locking-in effects, while others gave insignificant results. Heiborn’s results were not stable over different specifications, so it is hard to draw any firm conclusions from her study.

Westerlund (1998) studied the effects of mobility grants, labour market training, and relief work on mobility across county borders. Mobility grants had a marginally significant positive effect on total migration, while training and relief work gave significant locking-in effects. Looking separately at migration of the unemployed and the employed, all programmes had a positive effect on the mobility of the unemployed and a negative effect on other (potential) movers.

Widerstedt (1998) estimated models of individuals’ mobility probabilities, but found no significant effects of ALMPs.

Fredriksson (1999), finally, looked at regional adjustments to employment shocks at the county level. The main finding was that the bulk of the adjustment burden falls on mobility: ALMPs lower mobility marginally, and, hence, locking-in effects seem to dominate.

The results concerning geographical mobility are thus mixed. But most of the evidence suggests that ALMPs have reduced mobility. However, none of the studies have considered the job broking activities of the employment of-
fices. In addition, most of the studies do not distinguish between subsidised employment and labour market training.\textsuperscript{14}

### 4.2 Direct crowding-out (displacement)

As discussed in Section 2.5, subsidised employment is likely to cause direct displacement. The studies of this fall into two categories: (i) \textit{survey} studies; and (ii) \textit{econometric} studies of labour demand.

#### 4.2.1 Survey studies

In a number of surveys, employers, programme participants and employment officers have been asked whether they (i) believe that the work performed by programme participant(s) would have been performed by \textit{anyone} in the absence of the programme (\textit{substitution effects}); and (ii) in some cases, if this question was answered in the affirmative, whether the same person(s) would have been employed (\textit{deadweight effects}).

Such surveys suffer from a number of problems. First, participants may have an exaggerated view of their importance for the activity concerned. This could lead to an upward bias in the estimated displacement. Second, both employers and employment officers have incentives to avoid the impression that programmes are abused, which could give a bias in the opposite direction. Third, respondents are not likely to be able to evaluate the extent to which programmes crowd out employment in other workplaces than that associated with the programme.

A number of survey studies are summarised in \textit{Table 8}. Although the results vary considerably, all studies but one indicate that direct displacement occurs. In most cases the estimated displacement is substantial.

\textsuperscript{14} \textit{A priori}, it seems likely that subsidised employment would be associated with geographical locking-in effects. Regarding training, the case is not so clear: on one hand, training can be a substitute for geographical mobility, on the other hand, training may provide the trainee with skills that are valuable outside the home region.

Notes:

b. The Ministry of Labour commissioned the study and the results were reported in Ams (1997).

c. This refers to answers to the question whether the participant believes that the employer actually could have afforded to hire someone in the absence of the programme.

d. The fraction that answered "Yes, in most cases".

A way to summarise the information in Table 8 is to compute the average displacement for each programme according to the studies shown. The results are reported in Table 9, where the programmes have been ranked according to the size of the average displacement effect. There is a clear tendency that the closer to the regular labour market a programme is, the larger is the estimated displacement. For recruitment subsidies, trainee replacement schemes, general employment subsidies, and targeted employment subsidies, the estimated displacement effects are between 39 and 84 percent.

---

15 The table should be interpreted with caution, as the averages derive from studies using different methods, and some programmes have been subject to a large number of studies and others to only a few ones.

In addition to the studies in Table 8, a number of earlier studies (Peterson and Vlachos, 1978; Ams, 1981; Ams, 1983; Ams, 1985; RRV, 1989) used survey methods to estimate the total employment effects of temporary or permanent wage subsidies. The identified employment effects were generally small. So, these studies, too, suggest substantial displacement.

4.2.2 Econometric studies of direct displacement

The econometric studies identify the relationship between programmes and regular employment by comparing actual employment with the employment that would have been realised in the absence of programmes. Most of the studies have estimated traditional labour demand schedules augmented with measures of the volume of programmes.

A fundamental problem for econometric studies of direct displacement is that the relation between programmes and employment goes both ways: employment may depend on programme participation, but the size of programmes is also likely to depend on (un)employment. This simultaneity problem, discussed in the introduction to Section 4, may give rise to biased estimates of the effects of ALMPs. The problem is considered in different ways and to a various extent in the studies.

The econometric studies of displacement are much fewer than the survey studies. The results are summarised in Table 10.

Table 10 Econometric studies of direct displacement

<td></td>
<td></td>
</tr>
</tbody>
</table>
A first econometric study of direct displacement was carried out by Gramlich and Ysander (1981) using aggregate data for the period 1964–77. Their results were that relief work in road construction crowded out 100 percent regular employment, whereas there was no significant effect of relief work in health and welfare.

Forslund and Krueger (1997) used panel data for counties for a period encompassing the 1980s. Their results were similar to those of Gramlich and Ysander. Forslund and Krueger found significant displacement (36 percent – 69 percent) in the construction sector, but no significant effects for health and welfare. The authors handled the simultaneity problem in two ways. First they ran vector autoregressions to check whether relief work “explains” employment or if it is the other way around. Second, they estimated “displacement equations” for a sector where there should be no displacement.16 The results indicated that the effect is from relief work to employment and not the other way around.

Forslund (1996) and Dahlberg and Forslund (1999) used data at the municipal level. They distinguished between subsidised employment, relief work and labour market training.17 Subsidised employment and relief work were found to give displacement effects of around 65 percent, while there were no

---

16 Forslund and Krueger estimated a displacement effect for the durable manufacturing sector, in which there were no relief works. Such estimates test whether or not the displacement results are only spuriously reflecting cyclical patterns in both employment and relief work.

17 Relief work was singled out as a separate category to allow comparisons with earlier work.
significant effects of training. Dahlberg and Forslund treated the simultaneity problem in several ways, including IV (instrumental variables) estimations.

Sjöstrand (1997) claimed in a comment to Forslund (1996) that the analysis of the latter was built on a mis-specified model and that one finds no displacement effects with a correctly specified model. Löfgren and Wikström (1997) reviewed Forslund (1996) and Sjöstrand (1997) and found shortcomings in both studies. With the preferred specification of Löfgren and Wikström, only youth programmes gave rise to displacement (94 percent).

Edin, Forslund and Holmlund (1999) analysed the effects of youth programmes on youth employment and found large displacement effects (76 percent evaluated at the means of the variables). The simultaneity problem was handled mainly by means of IV methods.

Generally, the econometric studies give higher estimates of displacement than the survey studies. Typical figures are well above 60 percent. One possible explanation for the difference in results is that displacement is partly the result of distorted competition. Such effects are clearly difficult to assess for the respondents in survey studies. Another difference between the two types of studies is that many of the econometric investigations do not distinguish between different programmes. Hence, the effects are averages over several programmes. As an example, both work experience schemes and youth practice were included in “subsidised employment” in Dahlberg and Forslund (1999). The average displacement effect for subsidised employment in this study was 65 percent. This figure would, for example, be consistent with youth programmes crowding out significantly more than 65 percent and work experience schemes crowding out significantly less.

Most of the studies of displacement effects have tried to handle the simultaneity problem discussed in the introduction to Section 4 through various methods. The fact that the studies have not found displacement effects of labour market training (although the size of training programmes can be expected to change in response to the employment situation in a similar way as subsidised employment) also suggests that the relationships found reflect the effect of programmes on employment rather than the other way around.
4.3 Labour force participation

The effects of ALMPs on labour force participation is yet another area where research efforts have been modest. We are aware of only three studies that deal directly with the issue: Wadensjö (1993), Johansson and Markowski (1995), and Johansson (2001). All studies indicate strong positive effects of ALMPs on labour force participation.

One can also obtain indirect evidence on the labour force effects of ALMPs from studies of direct displacement. If ALMPs have a positive effect on labour force participation, the estimated crowding-out effects should be larger when employment is measured relative to the population than when they are measured relative to the labour force. This was indeed the case in Löfgren and Wikström (1997) and Dahlberg and Forsslund (1999).

However, the results on labour force participation should be interpreted with caution. If programme participation has been used as a means to renew eligibility for unemployment benefits, the increase in labour force participation has not necessarily meant an increase in effective labour supply.

4.4 Wage setting

For a number of reasons discussed in Section 2, ALMPs may affect wage setting. The mechanisms involve effects on matching, the competition in the labour market, the welfare and productivity of job seekers, and the allocation of the labour force across sectors. The net effect is theoretically unclear. Estimates of wage-setting schedules can throw light on this issue. A large number of such studies have been undertaken. In all cases, real wage equations including measures of unemployment and the volume of labour market programmes as explanatory variables have been estimated. The main results are summarised in Table 11.

Table 11 shows mixed results. Many studies find that larger ALMPs increase wage pressure, but many studies do not find any significant effect. Only three studies (OECD, 1993; Okeke, 1998; Thomas, 2000) suggest that ALMPs may reduce wage pressure. Most studies do not distinguish between different programmes. No consistent pattern emerges from the three studies (Löfgren and Wikström, 1991; Forslund, 1992; Edin, Holmlund and Östros, 1994) that estimate separate effects of labour market training and relief work.

Most of the studies cover periods ending before the deep recession of the 1990s. As both unemployment and ALMPs reached peak levels during this recession, it is uncertain to what extent the results from earlier studies apply to the 1990s. To the extent that compensation levels in programmes were lowered and the expected treatment effects on the probability of finding a job or on future income deteriorated, one should expect less unfavourable (or more favourable) wage effects of ALMPs. However, Johansson et al. (1999), Rødseth and Nymoen (1999), and Forslund and Kolm (2000) did not find any significant changes in the wage-setting behaviour between the 1990s and earlier periods.
Simultaneity problems of the same kind as for studies of displacement effects may be present also in the estimation of wage effects. However, because it probably takes time for wage changes to influence employment and for employment changes to trigger changes in programme volumes, the problem is likely to be less severe in this case. A more serious problem may be that programme participation covaries with long-term unemployment, so that adverse wage-setting effects of ALMPs could reflect that higher long-term unemployment reduces the competition for jobs that insiders meet (see Section 2.2).

4.5 Reduced-form estimates

A last type of studies is reduced-form estimates of the effects of ALMPs on (un)employment, i.e. estimates of the total net effects through all channels discussed in Section 2. Put differently, these estimations examine how the intersection between the wage-setting and employment schedules in Figure 4 is affected by the size of ALMPs.

The results from four reduced-form studies are summarised in Table 12.

Ohlsson (1993, 1995) estimated vector autoregressions (VARs) on aggregate quarterly time-series data. The estimated model was used to study the effects of an expansion of subsidised employment. The result was displacement in the order of magnitude of 50 percent during the first quarter. During later quarters the estimates are too imprecise to warrant any conclusions. Ohlsson also looked at the effects of both subsidised employment and labour market
training on wage setting, but found no significant effects. This was also the case for the effects of training on unemployment.

Skedinger (1995) estimated VARs to analyse the effects of subsidised employment for youth on regular youth employment. The results imply more than total displacement as soon as after one quarter. The effect becomes smaller over time (partly because programme volumes decline), but is statistically significant during the first five quarters.\(^{18}\)

Forslund (1995) estimated a reduced-form unemployment equation. The results indicated that ALMPs lead to lower open unemployment in the short run, but not in the long run. This would indicate complete displacement in the long run.

Calmfors and Skedinger (1995), finally, studied the relationship between total unemployment on the one hand and subsidised employment and labour market training on the other hand using a panel of the 24 counties between 1966 and 1990. The authors tried to handle the simultaneity problem through instrumental variables methods (one assumption being that the composition of the political majority in a county influences the volume of ALMPs, because the social democrats have generally been more in favour of these programmes than the liberal-conservative parties). Subsidised employment was found to cause large displacement effects (of the order of magnitude of 60–90 percent), whereas the results for training were very unstable.

To summarise, the reduced-form studies suggest that subsidised employment schemes tend to reduce regular employment, but also that they probably contribute to lower open unemployment.

### 4.6 Conclusions from the macroeconomic studies

Just as in the case of microeconomic studies, the overall picture from the macroeconomic studies of ALMPs in Sweden is rather disappointing. There is little evidence that ALMPs make the matching process more efficient; rather the studies of geographical mobility suggest the opposite. There is evidence of large direct displacement effects of those job creation schemes that most closely resemble regular employment, but not of labour market training. Some

\(^{18}\) Holmlund (1995) criticised Skedinger’s assumption that aggregate unemployment is exogenous, and showed that displacement falls to 40 percent if this assumption is dropped. Skedinger’s analysis was also criticized by Sjöstrand (1996a). See also Sjöstrand (1996b) and Skedinger (1996a, b).
evidence indicates that programmes tend to raise wage pressure, whereas other evidence does not point in this direction. Reduced-form estimates seem to show that programmes (at least subsidised employment) tend to reduce regular employment, even though they may help reduce open unemployment. The most favourable effects of ALMPs refer to labour force participation, which seems to be increased by large programmes.

5 Reduced-form studies on OECD data

Beginning with the influential study by Layard et al. (1991), a large number of studies have tried to explain unemployment differences among OECD countries by differences in labour market institutions. The earlier studies explained cross-country variations in unemployment rates with cross-country variation in labour market institutions. Later studies have used panel data to exploit both cross-sectional and time-series variations. Most of these studies have examined the influence of ALMPs. As these studies have usually been interpreted to give very favourable results for ALMPs, it may be of some interest to compare them with the studies of Sweden that we have surveyed.

5.1 Main results

The results in the studies of the OECD countries cannot be directly compared with those in the studies of Sweden. The reason is that the former studies use measures of expenditures on ALMPs (the only comparable measures available for all OECD countries), usually spending per unemployed person as a fraction of GDP per labour force participant (which was introduced by Layard et al., 1991), as explanatory variables, and open unemployment as the dependent variable. This does not allow direct estimates of how total (and open) unemployment is affected by programme participation, i.e. of how much displacement occurs. To derive these effects, the results in the studies on OECD data have to be recalculated using certain assumptions. The Appendix describes how this was done. The results are shown in Table 13.

**Notes:**

a. The minus and plus signs indicate the signs of the effects on the respective variables. A zero indicates a non-significant effect. Numbers in parentheses indicate the calculated effect on the variable in question of an increase in the participation in ALMPs by 1 percentage point of the labour force.

b. According to conventional theory, the sensitivity of the real wage to variations in unemployment is negatively related to equilibrium unemployment (Layard et al., 1991; Nickell and Layard, 1999).

c. See the entry for Zetterberg (1995) above in the table.

Most of the studies reported in the table support the hypothesis that an expansion of ALMPs contributes to lower open unemployment. Two of the studies also show a larger effect on long-term than short-term open unemployment (Jackman et al., 1996; Nickell and Layard, 1999). This is, of course, to be expected, as programme placement can be used to interrupt long unemployment spells. However, looking at the calculated effects on total unemployment (the sum of open unemployment and programme participation), the picture is different. Some studies indicate that total unemployment increases when ALMPs expand, others that it decreases. A couple of studies also find insignificant effects. One study (Okeke, 2000) finds that ALMP spending according to some panel estimates contributes to higher employment, but that the effect is declining in the level of spending.19

### 5.2 The interpretation of the results

There is reason to suspect that the problem of simultaneity bias in the studies reported above is quite serious. The reason is that the Layard *et al.* measure of ALMPs used in most of the studies, i.e. spending per unemployed person as a

---

19 The model includes ALMP spending as both a linear and a squared term among the explanatory variables; the estimated coefficient for the linear term is positive, whereas the estimated effect of the squared term is negative. However, the measure of employment includes subsidised employment, but not labour market training, so the results are difficult to interpret, although it is clear that they are not compatible with complete crowding-out of regular employment. Cross-section estimates show a zero effect on the employment measure, which indicates a negative effect on regular employment (excluding subsidised employment).
fraction of GDP, is likely to covary negatively with unemployment (OECD,
1993; Forslund and Krueger, 1997). Some of the studies have just neglected
this problem. Others have tried to address it in various ways. OECD (1993)
substituted ALMP expenditure as a fraction of the mean wage multiplied by the
labour force, and Forslund and Krueger (1997) ALMP expenditure as a fraction
of GDP, for the Layard et al. measure. In both studies the introduction of the
alternative measure resulted in insignificant estimates of the effects on open
unemployment.

Elmeskov et al. (1998) used the average of the Layard et al. measure over
the whole time period studied in order to reduced the problems of simultaneity,
whereas Nickell and Layard (1999) divided ALMP expenditures by the number
of unemployed persons in an earlier time period. According to the first study,
ALMPs have an insignificant, negative effect on total unemployment, whereas
they have a significant positive effect according to the second study.

On the whole, the conclusion seems to be that the results of ALMPs appear
less favourable when the problem of simultaneity bias is addressed. One should
also note that the reported results refer to unemployment as a share of the la-
bour force. We discussed in Section 4.3 that results may be more favourable
for ALMPs if unemployment is instead measured as a fraction of the popula-
tion, as the programmes may influence labour force participation positively.
Two of the studies on OECD data are consistent with such an effect. Nickell
and Layard (1999) did not find any significant decreasing effect of ALMPs on
employment as a fraction of the population at the same time as their results
imply an increase in total unemployment as a fraction of the labour force.
Scarpetta (1996) found that ALMPs contribute to a lower share of inactive per-
sons in the population.

6 Conclusions

Section 6.1 summarises the lessons regarding the various mechanisms through
which active labour market policy can work and the evidence on net employ-
ment effects. Section 6.2 draws conclusions on the relative efficiency of vari-
ous ALMPs. Section 6.3, finally, makes a tentative evaluation of active labour
market policy in Sweden and draws some general policy conclusions.
6.1 The various mechanisms of ALMPs
The empirical studies surveyed highlight the following mechanisms or complexes of mechanisms of active labour market policy: (i) effects on the matching process and the competition for jobs, as well as on productivity and the allocation of labour; (ii) direct crowding-out effects; (iii) effects on the wage pressure in the economy; and (iv) the net effect on regular employment (and open unemployment).

6.1.1 Matching efficiency and the competition for jobs
The effects on matching efficiency and the competition for jobs are highlighted in both microeconomic and macroeconomic studies. These effects are likely to be correlated with the effects on the productivity of job seekers and the allocation of labour (to the extent that ALMPs raise the productivity of the participants and re-allocate labour from low-demand to high-demand areas, matching efficiency and the competition for jobs are also likely to increase). On the whole, there is little support for the view that the active labour market policy in Sweden in the 1990s had positive effects in these respects.

Macroeconomic studies of geographic mobility seem to imply that ALMPs have rather tended to lock in labour. Although the microeconomic studies of the effects of labour market training on individuals in the 1980s found positive employment and income effects, this does not apply to the 1990s: the studies of the later period have instead usually found insignificant or negative effects. There are fewer studies of subsidised employment, and here the results vary more (see Section 6.2 below).

The most favourable results for the effects of ALMPs on individuals are obtained in survey studies of employer attitudes. But on the other hand, participants in ALMPs seem to search less actively for jobs than the openly unemployed while in programmes (although one study indicates that they are searching more actively after programme completion).

There is also some evidence that ALMPs in Sweden may have raised labour force participation, which might potentially lead to more competition for jobs. But the number of studies is too small to warrant more definite conclusions. There is also the question to what extent such a "registered" increase in
labour force participation translates into effective supply rather than just raising the possibilities to collect benefits.

6.1.2 Direct displacement
Both survey studies and econometric macro studies indicate that job creation schemes have crowded out regular employment to a substantial degree. Labour market training does not appear to have had such effects. The direct crowding-out effects are considerably larger in the econometric studies (usually around 60–70 percent) than in the survey studies (usually 15–40 percent).

6.1.3 Wage pressure
The effect of ALMPs on wage pressure is the net of a number of effects that work in different directions: effects on matching efficiency, competition effects, accommodation effects, effects on reservation wages and re-allocation effects. A large number of Swedish studies of the wage-setting relationship has examined this net effect. The results are not clear-cut. Many studies have found that an expansion of ALMPs has increased wage pressure. Nearly as many studies have found no significant effect at all. Fewer studies have found a wage-reducing effect. The conclusion is that Swedish ALMPs are unlikely to have reduced wage pressure, but it is unclear whether they have raised wages or had no effect at all.

6.1.4 The net effect on regular employment and unemployment
The net effects of ALMPs on (un)employment in Sweden have been studied in macroeconomic estimations of reduced-form equations. Most of the studies imply that an expansion of ALMPs reduces open unemployment. But the studies also suggest that the sum of direct and indirect crowding-out effects is large. The estimates do not support the view that an expansion of ALMPs reduces total unemployment (the sum of open unemployment and programme participation). Some of the evidence rather suggests the opposite.

We compared Swedish reduced-form estimations with similar estimations on cross-country and panel data for the whole OECD area. The latter studies have often been interpreted to give a very favourable picture of the employment effects of ALMPs (see e.g. Layard et al., 1991; or Nickell and Layard, 1999). This is, however, partly a misunderstanding, which derives from the fact
that these studies have usually focused on the effect on open unemployment rather than on regular employment or total unemployment. If one recalculates the estimates in these studies to effects on total unemployment, the effects vary between studies, but the overall picture is similar to the one from the Swedish studies.

6.2 The relative efficiency of various ALMPs
What do the studies of Sweden say about the relative efficiency of different programmes? A first issue concerns labour market training versus subsidised employment. Here, the microeconomic studies of effects on individuals and the macroeconomic studies of general-equilibrium effects give inconsistent results. The microeconomic studies of labour market training in the 1990s found no or negative employment effects. In contrast, some studies found positive effects of subsidised employment on later regular employment. But in the macroeconomic studies, there is a strong tendency that labour market training gives more positive (or less negative) effects on regular employment than subsidised employment. Only the latter programmes seem to cause direct crowding-out effects.

Another issue concerns the relative efficiency of various job creation programmes. The few available microeconomic studies suggest positive employment effects on the participating individuals of self-employment grants, recruitment subsidies, work placement schemes and trainee replacement schemes, whereas it has proved difficult to find such effects of relief work and work experience schemes. But at the same time, there is much to suggest that these programmes have large crowding-out effects. Unfortunately, there is a strong tendency that the schemes close to regular jobs have both positive employment effects for the participating individuals and large negative crowding-out effects.

The empirical studies seem to be the most negative for youth programmes. Here, there appear to be large crowding-out effects, at the same time as it is uncertain whether there are positive employment effects on the participating individuals.
6.3 Policy conclusions
Which policy conclusions can be drawn from the unique Swedish experiment in the 1990s of using large-scale ALMPs to fight high unemployment? Should the Swedish policy be followed by other countries in similar circumstances? It is true that enough time may not yet have passed to allow a final verdict: this may require an analysis of to what extent the rise in unemployment in the early 1990s will lead to persistent effects, and of whether there are long-term employment effects of ALMPs on labour force participation that have not yet worked themselves out. We do not rule out such effects. Notwithstanding these caveats, our conclusion is still that the labour market policy followed in Sweden in the 1990s was not efficient. The Swedish experience shows clearly the limitations of ALMPs as a measure to fight unemployment. It is not a measure that should be relied on to the extent that was done in Sweden.

A main problem with ALMPs in Sweden in the 1990s was their size. This applies especially to labour market training. It is a problem to expand training programmes very rapidly in a situation when the appropriate infrastructure is not there. In such a situation, one should expect marginal returns to be decreasing, as is suggested by Björklund and Moffitt (1987), who found the average effect on the hourly wage to be decreasing with the volume of training. One should also expect training programmes to be ineffective in a situation with very low demand, when unemployment duration is long under all circumstances, and when it is difficult to know where future labour shortages in the economy will appear. The upshot is that training programmes should be kept rather small in a deep recession. There is certainly a strong case for not using ALMPs (especially training programmes) as an income support measure (either as an alternative to unemployment benefits or as a means to re-qualify the participants for such benefits) as was done in Sweden, because this is likely both to distort the incentives for programme participation and result in very large programme volumes.

As to subsidised employment, we have pointed to the conflict between positive employment effects on the participating individuals and the macroeconomic crowding-out effects. This is a strong argument to target job creation measures on the long-term unemployed (and those who are threatened to be-
come long-term unemployed): then competition effects may affect regular employment positively, even if there are large crowding-out effects.

Our survey also questions the use of large-scale youth programmes, as they seem to have large displacement effects, at the same time as it is unclear whether there are any positive employment effects for the participating individuals. Since those who have been unemployed for less than six months seem rarely to meet negative employer attitudes (Klingvall, 1998), there appear to be no strong reasons to place young people in programmes during their first half-year of unemployment. This is an argument for much smaller youth programmes than were used in Sweden in the 1990s.

One cannot, of course, analyse the proper role of ALMPs without corresponding evaluations of alternative policy instruments. Indeed, subjecting only some policies to critical scrutiny, but not others, could lead to a worse policy mix. But it is safe to conclude that the Swedish strategy of using ALMPs as the main policy instrument to fight unemployment in the 1990s was not founded on systematic ex ante knowledge of the effectiveness of the programmes, and that our ex post evaluation does not support the view that they were effective in maintaining regular employment. Rather, the policies that were pursued are likely to have reduced open unemployment at the cost of also reducing regular employment. It is a value judgement whether one should consider this to reduce or increase social welfare. But there is a lot to suggest that the Swedish example of the 1990s is not one to follow if one views high regular employment as the primary objective of labour market policy.
Many of the studies on data from a large number of OECD countries discussed in Section 5 have estimated unemployment equations of the form

\[ u = \alpha \gamma + \ldots, \]  

(A1)

where

\[ \gamma = b_r r/y. \]  

(A2)

\( u \) is open unemployment (as a fraction of the labour force), \( \gamma \) is the measure of ALMPs, \( \alpha \) is a parameter measuring the effect of ALMPs on open unemployment, \( b_r \) is the expenditure on ALMPs per programme participant, \( r \) is programme participation (as a fraction of the labour force) and \( y \) is GDP per capita.

We are interested in computing \( du/dr \) and \( d(u+r)/dr \) from the estimated models. To do this, we substitute (A2) into (A1) and differentiate implicitly. This gives

\[ \frac{du}{dr} = \frac{(b_r/y)\alpha u}{u^2 + (b_r/y)\alpha r}. \]  

(A3)

To calculate \( du/dr \) we need information on \( b_r/y \). In our calculations we set \( b_r/y = 0.5 \). This parameter value is motivated in the following way. For Denmark, Finland, Norway and Sweden, Zetterberg (1995) provides information on \( \gamma \). The database collected by Rødseth and Nymoen (1999) gives information on programme participation and unemployment for the same countries. As \( b_r/y = \gamma u/r \), we can compute this ratio. The average values for the period 1985 – 91, are 0.41 for Denmark, 0.60 for Finland, 0.42 for Norway and 0.44 for Sweden.

As the effect on unemployment of ALMPs in (A3) is increasing in \( b_r/y \), our guesstimate 0.5 does not seem to imply that we have underestimated the effect systematically. Given this assumption, we can compute \( du/dr \) at given values of open unemployment and programme participation. The effect on total un-
employment (the sum of programme participation and open unemployment) is obtained as \( \frac{d(r+u)}{dr} = 1 + \frac{du}{dr} \).

Zetterberg (1995) instead used the ratio between total ALMP expenditures and total expenditures on the unemployed (see Table 1) as the measure of ALMPs in his unemployment equations. This measure, which we label \( \lambda \), can be written

\[
\lambda = b_r r / (b_r r + b_u u), \tag{A4}
\]

where, in addition to the previously explained variables, \( b_u \) is the expenditure per openly unemployed person. Here, we proceeded by assuming that the spending per programme participant equals the spending per openly unemployed, i.e., \( b_r = b_u \). Given this assumption, and given an estimated effect \( \beta = \frac{du}{d\lambda} \), we have in this case that

\[
\frac{du}{dr} = \frac{\beta u}{(u + r)^2 + \beta r} \tag{A5}
\]

In Table 15 in the text, we have assumed throughout that \( u = 0.07 \) and \( r = 0.03 \).
